Abstract

We study the computation contests where players compete for searching a solution to a given problem with a winner-take-all reward. The search processes are independent across the players and the search speeds of players are proportional to their computational powers. One concrete application of this abstract model is the mining process of proof-of-work type blockchain systems, such as Bitcoin. Although one’s winning probability is believed to be proportional to his computational power in previous studies on Bitcoin, we show that it is not the case in the strict sense.

Because of the gaps between the winning probabilities and the proportions of computational powers, the Matthew effect will emerge in the system, where the rich get richer and the poor get poorer. In addition, we show that allowing the players to pool with each other or reducing the number of solutions to the problem may aggravate the Matthew effect and vice versa.

1 Introduction

In a computation contest, a group of players compete with each other on solving a given computational problem and only the player who first finds a solution to this problem will receive a fixed reward. To solve the problem, the most efficient way is to execute a random brute force search across the candidate set, so the computational power is a critical resource for each player to increase the probability of winning this contest. Practical examples abound, ranging from tuning the parameters for a deep neural network, selecting random seeds for reinforcement learning to recovering the spatial structure of proteins and discovering new drugs for cancers [Cooper et al., 2010; Horowitz et al., 2016; Mnih et al., 2015; Silver et al., 2017a,b].

The mining process of *Bitcoin* [Nakamoto, 2008] is a concrete example that perfectly matches the computation contest in terms of mathematics. The Bitcoin system is maintained as a chain of blocks and it awards the builder of each block by a certain amount of BTC, which is about 12.5 BTC ($\approx 79,400$ USD) at the time this paper is written. To build (or mine) a block, one must find a block header (a fixed-length bit string) whose hash value meets a certain criteria and announce it before other competitors. Because it is hard to invert the secure hash function, the most efficient way is to enumerate (in an arbitrary order) and verify the candidate block headers. This is exactly the case as we described in the computation contest and the mining process is now an extremely fierce competition – the total computational power of the community is roughly 48E (4.8×10^{19}) hash per second.¹

To participate such a vast contest, understanding the winning probability or the expected reward is undoubtedly important to the players. So far, the winning probability of each player is believed to be proportional to his computational power (or his speed of verifying one candidate) [Fisch et al., 2017]. Their argument is briefly as follows: For each player, the wins follow a Poisson process with a strength proportional to his computational power and hence the expected reward is also proportional to his computational power.

However, in the strict sense, this conclusion is incorrect due to the nature of draws without replacement in the computation contests: Conditioned on no solution has been found yet, the more candidates one has already checked, the higher probability the next candidate will be a solution. To see this concretely, take the following extreme case as an example. There are only two players with computational powers being 2 and 1. When there is only one solution to the given problem, the winning probabilities of them are in fact 3/4 and 1/4, instead of 2/3 and 1/3. In Section 3,

¹See <https://www.blockchain.com/en/charts/hash-rate>.

we will demonstrate the analysis in details. In general, our analysis shows that the gap between one’s winning probability and the proportion of his computational power increases as the number of solutions of the problem decreases.

Such gaps, if not negligible, will lead to the Matthew effect in the system where the players repeatedly participate the computation contest. In practice, the reward received now often results in increments of computational powers in the future, for example, research groups can attract more researcher and funds by their results and Bitcoin miners can purchase more machines using BTCs. The gaps, as we will show in this paper, offer higher increments for those with relatively high computational powers and makes *the rich (relatively) richer and the poor (relatively) poorer*. Eventually, the entire system could be dominated by a single player, which is undesirable in most applications. The converging speed could be accelerated if the players are allowed to form groups or *pools* where they can jointly search for the solution and split the rewards.

Our analysis of the computation contest then suggests that keeping the number of solutions large is critical to suppress the Matthew effect in the system.

1.1 Our contribution

In this paper, we make the following contributions, where all the results apply to general multiple-solution cases:

- We give the winning probabilities of the players in closed-form, both for the single-solution case (Theorem 1) and the multiple-solution case (Theorem 9).
- In general, the probabilities are *not* proportional to the computational powers of the players. In extreme cases, this may lead to *the Matthew effect* in terms of computational powers: “the rich get richer and the poor get poorer”.
- We introduce a pool choosing game between the players, where each of them can either specify one pool to join or keep himself independent. We analyse the incentives of the players under this game (Section 4) and identify a non-trivial Nash equilibrium (Theorem 4).

In particular, in the Nash equilibrium, there is always a pool (or a single player) who has more than half of the total computational power. It implies that the Matthew effect could become even stronger when pooling is allowed. For the application of Bitcoin, it also means the 51% attack² could emerge in this case.

- Last but not least, we show that increasing the number of solutions will mitigate the Matthew effect. This is because as the number of solutions grows, the winning probabilities will gradually get close to being proportional to computational powers, where the gap between the probabilities and the proportions can be roughly bounded by the order of n^{-1} (Theorem 11).

1.2 Related work

The blockchain and Bitcoin are first presented in 2008 under the pseudonym Nakamoto [2008] and widely concerned in the past decade. Thousands of papers follow the work by Nakamoto [2008] with research areas including cryptography, game theory, and distributed systems. The book “Mastering Bitcoin” [Antonopoulos, 2014] introduces the basic knowledge about Bitcoin for beginners and Tschorsch and Scheuermann [2016] summarize some early studies and progresses of the Bitcoin techniques.

The game-theoretical analysis of the mining systems, where each miner performs as a self-interested player to maximize his reward, is one of the central topics of blockchain researches and most relevant to this work. Rosenfeld [2011] introduces the attack called “pool-hopping”, where the miner can work in one pool at the beginning of one round and hop to another pool when the current round is longer than a threshold, and analyzes the advantages and disadvantages under several reward mechanisms of mining pools. Eyal and Sirer [2018] introduce the attack called “selfish mining”. In such an attack, when a miner successfully mines a block, he can choose to not publish it and continue mining based on that block, called the private chain. Results show that a rational miner will follow the selfish mining strategy as long as the selfish miner controls at least 1/3 of the total computational power. Kiayias et al. [2016] consider a mining game with similar attacks, where the model structure is a tree of blocks and a block

²The 51% attack is a concept in PoW blockchain systems [Tschorsch and Scheuermann, 2016]. It states that if one player (or a pool) has computational power more than half of the total computational power in the system, then he/she is able to manipulate the blockchain.

becomes valid when its height is larger than a given threshold. Eyal [2015] proposes an attack that a mining pool can send some “spies” to other pools and share the utilities of the spies obtained from these pools. Liu et al. [2018] consider how a miner should choose a mining pool of which the required computational power is fixed. Fisch et al. [2017] show that the geometric pay pool achieves the optimal social welfare based on the power utility function.

In the famous economic model, R&D race [Canbolat et al., 2012; Harris and Vickers, 1987], a similar setting is analyzed, where each agent can choose his effort rate to the winner-takes-all competition. However, the expected profits are still assumed to be linear to the agents’ effort rates with additional costs. To the best of our knowledge, no literature drops the assumption about the proportional winning probability and this paper is the first to mathematically consider the winning probabilities in first principles.

2 Preliminaries

Consider the following model of an abstract computation contest where the problem is solved via random trials:

- m players compete with each other in solving a problem;
- The problem is to find a solution of $h(v) = 0$ from a candidate set V , where $|V| = N$ is finite;
- There are $n \geq 1$ solutions to the problem, but only the player who first finds one solution receives a reward 1.

In particular, there is no trick for solving the problem in the sense that enumerating and verifying all candidates from V in an arbitrary order is the best algorithm. Formally, let h be randomly drawn from a ground set \mathcal{H} according to some distribution, such that for any $v \in V$, the event $h(v) = 0$ is independent of the function values of any subset of $V \setminus \{v\}$. In addition, the probability of $h(v) = 0$ is the same for any $v \in V$ and the computational resource needed to determine whether $h(v) = 0$ or not is the also the same for any $v \in V$, both independent of the knowledge about the function values on $V \setminus \{v\}$.³

Throughout the paper, we refer each $v \in V$ as a *candidate* and the ones such that $h(v) = 0$ as *solutions*. In the contest, each player i has a type $x_i > 0$ called the *computational power*, i.e., the number of candidates he can verify in a unit of time. The player with higher computational power will be able to test more candidates and of course has higher chance to win. Here, we assume that each player is enumerating through the candidate set in a random order independent of others.

Blockchain One concrete real-world example of this computation contest is the application of blockchains under Proof of Work (PoW) schemes. As its name would suggest, a *blockchain* is a chain of many blocks that are accepted by the peers, where each accepted block must have a valid *block header* pointing to the previous block.

Taking Bitcoin as the example: Each block header has a fixed length of 80 bytes (640 bits) which in general could be divided into two parts: (i) the fixed part (e.g., the hash value of the previous block header) and (ii) the adjustable part (e.g., the *nonce* and the *merkle root*). In other words, there is a fixed and finite set V containing all block header candidates.

A block header is valid if its hash value (a 256-bit integer) is less than a target threshold, i.e., $2^{208}(2^{16} - 1)/D \approx 2^{224}/D$, where D is a positive number called *difficulty*. In this case, the probability of a randomly selected block header being valid is $2^{224}/D \cdot 2^{-256} = 2^{-32}D$. In the language of our computation contest model, the function value $h(v)$ of a candidate block header v is 0, if and only if v is a valid block header.

Since the hash function is deterministic, for any specific block, the number of valid block headers (solutions), n , is fixed (but unknown). Note that the fixed part of block header is randomly determined by the previous block and the system, therefore it can be seen as the random index of the function h , given that the hash function is ideal.

The main computational challenge of building the next block is to find one of the n valid block headers from the N possible candidates, or equivalently, solving $h(v) = 0$. In particular, if the hash function resists preimage attacks, the most efficient algorithm one can hope for is the brute force search (in arbitrary orders). In the context of blockchain, the procedure of searching a valid block header is referred as *mining* and the speed of computing the hash function is often referred as the *hash rate* or the computational power.

³Although the assumption here can hardly be exactly met in real applications, our analysis still applies at some extent. For example, in the case of blockchain under PoW schemes, the hash function h is fixed and so are its solutions. However, as long as the hash function is still secure, the algorithmic advantage of solving the problem is negligible and every one is searching in a random order. As a result, the probability of the t -th candidate v_t being a solution is still a constant.

In the classic PoW scheme, such as Bitcoin, every miner has the equal right to mine and the one who first announces the next block with a valid block header will win the reward on that block. The reward is a constant with respect to the mining procedure. Therefore, the mining process of each block could be well-modeled by our computation contest, where each miner corresponds to a player, block headers correspond to candidates, and valid block headers correspond to solutions.

Pooling In practice, the probability of winning the contest could be extremely low for a single player and hence the variance of the random reward is very high. To avoid the high variance, it is a common practice that individuals form a *pool* and jointly search for the solution. Once the pool wins, the reward will be distributed to the players in the pool according to a pre-specified policy. The most common policy, in the case of Bitcoin, is essentially a proportional allocation rule, i.e., the reward a player receives is proportional to the computational power he contributes to the pool.⁴ In the same spirit, work by Bloch [1996] analyzes sequential coalition game, splitting the whole party into subsets, and studies subgame perfect equilibrium.

In this paper, we focus on two types of questions under this computation contest model:

- Given the environment and the computational powers, what are the winning probabilities of the players? Are the probabilities proportional to their computational powers?
- If not proportional to their computational powers, what is the optimal pooling strategy for the players?

3 The Single-Solution Case

In this section, we start with the basic case with only one solution, i.e., $n = 1$. Later in Section 5, we will generalize all results for single-solution cases to multiple-solution cases.

3.1 Warmup: two players and a single solution

As defined in the previous section, the player who find its first solution earliest wins. To compute the winning probabilities of the players, we use real numbers in $[0, 1]$ to index the candidates in the order that they are verified by player i .⁵ Since each candidate in general will have different indices in the enumerating sequences of different players, putting the indices together, a *coordinate* of each candidate is defined. In particular, let t_i be the index of the first solution in player i 's sequence and then t_i/x_i is the time that player i first finds a solution. In this case, the player with minimum t_i/x_i wins. Note that the t_i 's are random variables and also the source of the randomness of the outcome.

Let p_i be the winning probability of player i , we have

$$p_i = \Pr[i \text{ wins}] = \Pr \left[t_i/x_i \leq \min_{j \neq i} t_j/x_j \right].$$

For the two-player single-solution case, since there is only one solution, t_1 and t_2 are independently and uniformly distributed over $[0, 1]$. Denote $\mathbf{t} = (t_1, t_2)$ and let T_1 be the set of \mathbf{t} where player 1 wins:

$$T_1 = \{\mathbf{t} \in [0, 1]^2 : t_1/x_1 \leq t_2/x_2\}.$$

Similarly, we can define T_2 :

$$T_2 = \{\mathbf{t} \in [0, 1]^2 : t_2/x_2 \leq t_1/x_1\}.$$

⁴As recorded on <https://investoon.com/mining.pools/btc>, the most common reward schemes in the pools are PROP, PPS, PPLNS, all with expected reward approximately proportional to their hashrates.

⁵Here we simplify the analysis by using real numbers to index the candidates. One can of course use the fractions k/N with integers $k < N$ to index the candidates for an even more rigorous analysis. In this case, our analysis still applies by replacing the integrations with summations. The only difference here is the break-ties at $t_i/x_i = t_j/x_j$. Their probabilities are zero under real number indexing but at order $1/N$ for fraction number indexing, which is also negligible for large N .

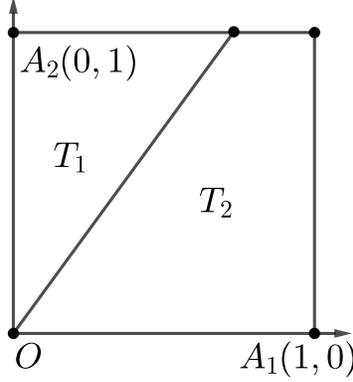

Figure 1: In the two-player case, player 1 wins if and only if the random coordinate t falls into T_1 .

Because t is uniformly distributed over $[0, 1]^2$, $p_1 = \int_{T_1} dt = \text{area}(T_1)$ equals to the area of set T_1 (see Figure 1). Suppose that $x_1 \leq x_2$, then with some primary calculation, we know that the slope of the line separating T_1 and T_2 is x_2/x_1 and hence

$$p_1 = \text{area}(T_1) = x_1/2x_2, \quad p_2 = \text{area}(T_2) = 1 - x_1/2x_2,$$

which are not proportional to the computational power x_1 and x_2 (unless $x_1 = x_2$).

3.2 m players and a single solution

For the general m -player case, the winning probability of each player is summarized by the following theorem, where $\pi(z)$ and $\pi_{-i}(z)$ are defined to simplify the notations:

$$\pi(z) = \prod_{i=1}^m \left(1 - \frac{x_i}{x_m} \cdot z\right), \quad \pi_{-i}(z) = \frac{\pi(z)}{1 - \frac{x_i}{x_m} \cdot z}.$$

Theorem 1. Suppose that $x_1 \leq x_2 \leq \dots \leq x_m$, then the winning probability of player i is:

$$p_i = \frac{x_i}{x_m} \int_0^1 \pi_{-i}(z) dz.$$

Proof. Recall that

$$p_i = \Pr \left[t_i/x_i \leq \min_{j \neq i} t_j/x_j \right] = \Pr \left[\bigwedge_{j \neq i} t_i/x_i \leq t_j/x_j \right].$$

Let $f_i(\cdot)$ be the probability density function of the random variable t_i , then

$$p_i = \int_0^1 \Pr \left[\bigwedge_{j \neq i} t_j \geq \frac{t_i x_j}{x_i} \mid t_i = t \right] f_i(t) dt.$$

Since the orders of the players enumerating through the candidates are independent, we have that

$$\Pr \left[\bigwedge_{j \neq i} t_j \geq \frac{t_i x_j}{x_i} \mid t_i = t \right] = \prod_{j \neq i} \Pr \left[t_j \geq \frac{t x_j}{x_i} \right].$$

In the meanwhile, note that t_1, \dots, t_m are uniformly distributed, hence $f_i(t) = 1$ and

$$\Pr \left[t_j \geq \frac{t x_j}{x_i} \right] = \max \left\{ 1 - \frac{t x_j}{x_i}, 0 \right\}.$$

Thus the production is zero for $t \geq x_i/x_m$, which implies

$$p_i = \int_0^{x_i/x_m} \prod_{j \neq i} \left(1 - \frac{tx_j}{x_i}\right) dt.$$

By substituting $t = x_i z/x_m$, we complete the proof

$$p_i = \frac{x_i}{x_m} \int_0^1 \prod_{j \neq i} \left(1 - \frac{x_j}{x_m} \cdot z\right) dz = \frac{x_i}{x_m} \int_0^1 \pi_{-i}(z) dz.$$

□

According to Theorem 1, the winning probabilities p_i are proportional to the computational powers x_i if and only if the integration $\int_0^1 \pi_{-i}(z) dz$ is a constant for all $1 \leq i \leq m$, which in general is not true.

In particular, as we will show in Section 5, the observation above holds even when there are multiple solutions, i.e., $n > 1$. Nevertheless, as n goes to infinity, the winning probabilities will gradually get close to being proportional with respect to the computational powers.

However, the larger the player's computational power is, the higher efficiency (winning probability divided by computational power) it achieves.

3.2.1 The Matthew Effect

The next theorem in fact indicates the Matthew effect in such systems: the player with higher computational power gets higher return (or higher probability to win) for each unit of their computational power, i.e., $p_i/x_i \leq p_j/x_j$.

Theorem 2 (The Matthew Effect). *If $x_i \leq x_j$, then $p_i/x_i \leq p_j/x_j$, where the equality is reached if and only if $x_i = x_j$.*

If both of them invest all the rewards (such as bitcoins) they get to increase their future computational power, the ratio of x_j/x_i will become larger and larger over time:

Δx_i and Δx_j are proportional to p_i and p_j , respectively, hence

$$\Delta x_i/x_i \leq \Delta x_j/x_j, \implies (x_i + \Delta x_i)/(x_j + \Delta x_j) \leq x_i/x_j.$$

In other words, the player with the highest computational power in the system will gradually take a more and more fraction of the total computational power and eventually dominate the entire system.

Proof of Theorem 2. To simplify the notations, write

$$\pi_{-ij}(z) = \frac{\pi(z)}{\left(1 - \frac{x_i}{x_m} \cdot z\right)\left(1 - \frac{x_j}{x_m} \cdot z\right)}.$$

Therefore, by $x_i \leq x_j \leq x_m$ and $\pi_{ij}(z) \geq 0$, we have that $\forall z \in [0, 1]$,

$$\left(1 - \frac{x_j}{x_m} \cdot z\right) \cdot \pi_{-ij}(z) \leq \left(1 - \frac{x_i}{x_m} \cdot z\right) \cdot \pi_{-ij}(z).$$

Finally, using Theorem 1, we conclude that

$$\frac{p_i}{x_i} = \frac{1}{x_m} \int_0^1 \left(1 - \frac{x_j}{x_m} \cdot z\right) \cdot \pi_{-ij}(z) dz \leq \frac{1}{x_m} \int_0^1 \left(1 - \frac{x_i}{x_m} \cdot z\right) \cdot \pi_{-ij}(z) dz = \frac{p_j}{x_j}.$$

In particular, the equality is reached if and only if $x_i = x_j$. □

4 Pooling Incentives

In this section, we investigate the incentives of players to pool together assuming that the reward is split proportional to their computational powers. In particular, we identify a non-trivial Nash equilibrium of the following *pool choosing game*.

Definition 3 (Pool choosing game). *Let $\mathcal{P}_1, \dots, \mathcal{P}_m$ be m pools. The actions of each player is either to choose one from these m pools (say \mathcal{P}_i) or to be independent (denoted as \perp). The utility of each player is the expected winning reward and if a pool wins, the reward is split proportional to its members' computational powers.*

In the practice of Bitcoin, there are many such pools. The pools have their own websites, cooperatively mining tools, and reward splitting policies. Usually, the pools always welcome miners to join so that they can attract more computational resources. In contrast, each individual miner can of course work by himself.

As a quick example, the action profile $(\mathcal{P}_1, \dots, \mathcal{P}_1)$ results in a giant pool including everyone ($\{1, \dots, m\}$) and the action profile (\perp, \dots, \perp) results in everyone being independent. Although trivial, the latter is a Nash equilibrium of the game. Because, for example, if player i deviates, then the result is that only player i in a pool and all others being independent. No difference.

The following theorem then identifies a non-trivial Nash equilibrium for two cases.

Theorem 4 (Nash Equilibrium). *Suppose that $x_m \geq x_{m-1} \geq \dots \geq x_1$. If $x_m \leq x_1 + \dots + x_{m-1}$, then the action profile $(\mathcal{P}_1, \dots, \mathcal{P}_1)$ is a Nash equilibrium, yielding a giant pool.*

Otherwise, we have $x_m \geq x_1 + \dots + x_{m-1}$, and the action profile $(\mathcal{P}_1, \dots, \mathcal{P}_1, \perp)$ is a Nash equilibrium, with player m being independent and the others in one pool.

To prove this theorem, we first need to understand the conditions that a player has incentive to join a pool (or another player). With the theorems and lemmas in place, we prove Theorem 4 at the end of this section.

We also emphasize that the results in this section will later be generalized to the multiple-solution case in Section 5.

4.1 Incentive Analysis

First of all, an important and immediate observation for pooling is that pooling is always beneficial when taking the pool as a whole. Formally,

Observation 5. *A pool's winning probability is no less than the sum of the winning probabilities of its members when they participate the computation contest separately.*

This is easy to get by considering a “pseudo-pool” of the members, where they enumerate through the candidates in the same order as they do when participate the contest separately. Clearly, the winning probability of the “pseudo-pool” equals to the sum of the winning probabilities of the members working separately. Since the players in the “pseudo-pool” may repeatedly verify some of the candidates, the winning probability could be even higher if they simply skip those already verified by other members in the pool. In particular, this “higher” winning probability equals to the winning probability of the real pool by symmetry.

Theorem 6. *For any player i , pooling with another player with higher computational power than him is always beneficial.*

Proof. Consider a player i pooling with another player j with $x_j \geq x_i$. We use p_{ij} to denote the winning probability of the pool. Then by Observation 5, we have $p_{ij} \geq p_i + p_j$ and hence the reward of player i from the pool is

$$p'_i = \frac{x_i}{x_i + x_j} \cdot p_{ij} = \frac{p_{ij}}{1 + x_j/x_i} \geq \frac{p_i + p_j}{1 + x_j/x_i}.$$

Note that by Theorem 2, we have

$$p_i/x_i \leq p_j/x_j \iff x_j/x_i \leq p_j/p_i.$$

Therefore

$$p'_i \geq \frac{p_i + p_j}{1 + x_j/x_i} \geq \frac{p_i + p_j}{1 + p_j/p_i} = p_i.$$

In other words, player i gets more reward by pooling with player j . □

A direct consequence of this theorem is that a pool is stable against single deviation as long as the largest player's computational power is no more than half of the computational power of the pool.

Corollary 7. *Any individual member of a pool has no incentive to leave if its computational power is no more than half of the pool's computational power.*

Proof. Otherwise, once the player left the pool, he would have incentive to rejoin the pool by Theorem 6, a contradiction. \square

In fact, the corollary asserts that any player (or pool) always has incentive to pool with a player (or pool) that has higher computational power than himself. In contrast, there would be a tradeoff for the player (or pool) being proposed:

- **Pros:** By pooling together, they form a larger pool, which by Theorem 2, has a higher efficiency in terms of computational power (i.e., higher ratio of reward divided by computational power).
- **Cons:** However, the player (or pool) with low computational power may actually takes more than he contributes. In this case, the total tradeoff for the player with high computational power could be negative and he would have incentive to be independent.

The following lemma then provides a sufficient condition where the tradeoff is positive.

Lemma 8. *If $x_i + x_j \leq x_m$, then both i and j will be better off in terms of the expected reward by pooling.*

Proof. Throughout the proof, we use the notations $\pi_{-ij}(z)$ (defined in the proof of Theorem 2) and p_{ij} (the winning probability of the pool $\{i, j\}$).

Without loss of generality, suppose that $x_i \leq x_j \leq x_m$. Then by Theorem 6, player i gets better off by pooling. In the rest of the proof, we show that player j gets better off as well.

On one hand, according to the proportional allocation rule, the reward of player j by pooling is $p'_j = \frac{x_j}{x_i + x_j} \cdot p_{ij}$. Thinking the pool $\{i, j\}$ as a player with computational power $x_i + x_j$, then by Theorem 1,

$$p_{ij} = \frac{x_i + x_j}{x_m} \int_0^1 \pi_{-ij}(z) dz.$$

Hence

$$p'_j = \frac{x_j}{x_i + x_j} \cdot p_{ij} = \frac{x_j}{x_m} \int_0^1 \pi_{-ij}(z) dz.$$

On the other hand, the reward of player j without pooling is p_j , which by Theorem 1 is,

$$p_j = \frac{x_j}{x_m} \int_0^1 \pi_{-j}(z) dz.$$

Note that for any $z \in [0, 1)$, since $x_i < x_m$ and $\pi_{-ij}(z) > 0$,

$$\pi_{-ij}(z) > \left(1 - \frac{x_i}{x_m} \cdot z\right) \pi_{-ij}(z) = \pi_{-j}(z).$$

Therefore,

$$p'_j > p_j.$$

In other words, player j gets strictly higher expected reward by pooling with player i . \square

4.2 Equilibrium Analysis

Now we are ready to prove Theorem 4.

Theorem (Theorem 4 restate). *Suppose that $x_m \geq x_{m-1} \geq \dots \geq x_1$. If $x_m \leq x_1 + \dots + x_{m-1}$, then the action profile $(\mathcal{P}_1, \dots, \mathcal{P}_1)$ is a Nash equilibrium, yielding a giant pool.*

Otherwise, we have $x_m \geq x_1 + \dots + x_{m-1}$, and the action profile $(\mathcal{P}_1, \dots, \mathcal{P}_1, \perp)$ is a Nash equilibrium, with player m being independent and the others in one pool.

Proof of Theorem 4. The first case is a direct consequence of Corollary 7. Because none of them has computational power more than half of the pool, no player has incentive to deviate (leave the pool).

For the second case, we first show that player m has no incentive to deviate (or equivalently, join pool \mathcal{P}_1).

We use x_{-m} and p_{-m} to denote the computational power and the winning probability of the pool $\{1, \dots, m-1\}$, respectively. Since $x_m \geq x_{-m}$, by Theorem 2, $p_m/x_m \geq p_{-m}/x_{-m}$. Note that $p_m + p_{-m} = 1$, hence $p_{-m} = 1 - p_m$. Then we have

$$\frac{p_m}{x_m} \geq \frac{1 - p_m}{x_{-m}} \iff p_m \geq \frac{x_m}{x_{-m} + x_m},$$

where the right-hand-side is the reward of player m if he joins the pool. In other words, if player m deviates by joining pool \mathcal{P}_1 , his winning probability will decrease.

Then we prove that any player $i \in \{1, \dots, m-1\}$ has no incentive to deviate (or equivalently, leave pool \mathcal{P}_1).

To show this, we prove that player i has incentive to join pool \mathcal{P}'_1 , when $\mathcal{P}'_1 = \{1, \dots, i-1, i+1, \dots, m-1\}$ and player m chooses \perp . Thinking the pool \mathcal{P}'_1 as a player with computational power $x' = x_1 + \dots + x_{i-1} + x_{i+1} + \dots + x_{m-1}$. Since $x_i + x' \leq x_m$, then by Lemma 8, player i has incentive to join pool \mathcal{P}'_1 . In other words, player i gets (weakly) higher reward in pool \mathcal{P}_1 than being independent.

In summary, for the second case, no player has incentive to deviate, hence a Nash equilibrium. \square

5 The Multiple-Solution Case

In this section, we first extend our results of single-solution cases to multiple-solution cases. Then we show that as the number of solutions goes to infinity, the winning probabilities become asymptotically proportional to the player computational powers. In particular, it means that the Matthew effect gets weaker as the number of solutions increases.

5.1 Generalization

We start with generalizing Theorem 1.

Theorem 9. *Suppose that $x_1 \leq \dots \leq x_m$, then the winning probability for player i in the multiple-solution case is*

$$p_i = \frac{x_i}{x_m} \int_0^1 \pi_{-i}(z) \cdot \pi(z)^{n-1} dz.$$

We omit the proof of this theorem but highlight the only two differences with the proof of Theorem 1. Both are because of the definition of t_i , the index of the first solution in player i 's sequence. Therefore, the probability density function of t_i and the probability that $t_j \geq tx_j/x_i$ are different with those in the single-solution case:

$$f_i(t) = n(1-t)^{n-1}, \Pr \left[t_j \geq \frac{tx_j}{x_i} \right] = \max \left\{ 1 - \frac{tx_j}{x_i}, 0 \right\}^n.$$

Then by substituting these two terms in the proof of Theorem 1, we get Theorem 9.

Based on Theorem 9, we claim that all previous results (except Theorem 1) also apply to multiple-solution cases:

Claim 10 (Generalization). *Theorem 2 and Lemma 8 can be easily reproved for multiple-solution cases with Theorem 9. Based on this, Theorem 4, Observation 5, Theorem 6, and Corollary 7 are automatically generalized because their proofs do not rely on the number of solutions.*

5.2 Asymptotically Proportional Winning Probabilities

Consider the probability that the first solution comes after t_1, \dots, t_m for each of the players. Since the distribution of each t_i is independent, we have:

$$\Pr[\tau \geq \mathbf{t}] = \prod_{i=1}^m \Pr[\tau_i \geq t_i] = \prod_{i=1}^m (1 - t_i)^n,$$

hence its density function:

$$f(\mathbf{t}) = \prod_{i=1}^n f_i(t_i) = \prod_{i=1}^n \frac{\partial (1 - t_i)^n}{\partial t_i} = n^m \prod_{i=1}^m (1 - t_i)^{n-1}.$$

Let T_i be the set of \mathbf{t} that player i wins and $T = T_1 \cup \dots \cup T_m = [0, 1]^m$. Then the winning probability of player i is

$$p_i = \int_{\mathbf{t} \in T_i} f(\mathbf{t}) d\mathbf{t}.$$

Theorem 11 (Asymptotically Proportional). *For any fixed number of players, m , as the number of solutions, n , approaches to infinity,*

$$p_i \longrightarrow \frac{x_i}{x_1 + \dots + x_m}.$$

In particular, the difference is vanishing in the order of $\tilde{O}(n^{-1})$,⁶ i.e.,

$$\left| p_i - \frac{x_i}{x_1 + \dots + x_m} \right| = \tilde{O}(n^{-1}).$$

The theorem could be directly derived based on the following Lemma 12 and Lemma 13.

We use $\rho_i(z)$ to denote the $(m-1)$ -dimensional volume of set $\{\mathbf{t} \in T_i : t_1 + \dots + t_m = z\}$ and $\rho(z) = \rho_1(z) + \dots + \rho_m(z)$.

Then Lemma 12 essentially means that p_i is asymptotically proportional to $\rho_i(1)$.

Lemma 12. *For any constant $m \ll n$,*

$$p_i = \frac{\rho_i(1)}{\rho(1)} \cdot n^m \int_0^{n^{-1+\epsilon}} (1-z)^{n-1} \rho(z) dz + \tilde{O}(n^{-1}).$$

Furthermore, Lemma 13 indicates that $\rho_i(1)$ is proportional to the computational power of player i .

Lemma 13.

$$\frac{\rho_i(1)}{\rho(1)} = \frac{x_i}{x_1 + \dots + x_m}.$$

Proof of Theorem 11. By Lemma 12 and Lemma 13. □

We dedicate the rest of this section to prove Lemma 12 and Lemma 13.

⁶The \tilde{O} notation here hides a poly-log factor, meaning that the residue term is bounded by $O(n^{-1}(\ln n)^c)$, for some positive constant $c > 0$ when n is sufficiently large.

Proof idea of Lemma 12 The proof is done by a careful estimation of p_i using a technique called the *core-tail decomposition* [Li and Yao, 2013]. To estimate the probability, consider the core-tail decomposition of the set T_i , i.e., let

$$\text{core} = \{\mathbf{t} : \bar{t} \leq \alpha\} \quad \text{and} \quad \text{core}(T_i) = \text{core} \cap T_i,$$

where $\bar{t} = t_1 + \dots + t_m$ and $\alpha > 0$ is a parameter to be determined later. Similarly, define $\text{tail} = [0, 1]^m \setminus \text{core}$ and $\text{tail}(T_i) = \text{tail} \cap T_i$. Thus,

$$p_i = \int_{\text{core}(T_i)} f(\mathbf{t}) d\mathbf{t} + \int_{\text{tail}(T_i)} f(\mathbf{t}) d\mathbf{t}. \quad (1)$$

The following two lemmas would be helpful on simplifying the analysis.

Lemma 14. *Let $g(\mathbf{t}) = n^m(1 - \bar{t})^{n-1}$. If $\alpha < n^{-2/3}$, then*

$$\int_{\text{core}(T_i)} f(\mathbf{t}) d\mathbf{t} = \int_{\text{core}(T_i)} g(\mathbf{t}) d\mathbf{t} + O(n^{m+1}\alpha^{m+2}).$$

Lemma 15.

$$\int_{\text{tail}(T_i)} f(\mathbf{t}) d\mathbf{t} \leq e^{-\alpha(n-1)+m \ln n}.$$

We postpone the proofs of these lemmas to Section 6, which are mainly elaborate treatments of the Taylor series.

Proof of Lemma 12. Plugging Lemma 14 and Lemma 15 into (1), and letting $\alpha = \frac{(m+1)\ln n}{n-1}$, we have that,

$$p_i - \int_{\text{core}(T_i)} g(\mathbf{t}) d\mathbf{t} = O(n^{-1}(\ln n)^{m+2}) = \tilde{O}(n^{-1}).$$

Hence we remain to show the following equation:

$$\int_{\text{core}(T_i)} g(\mathbf{t}) d\mathbf{t} = \frac{\rho_i(1)}{\rho(1)} \cdot n^m \int_0^\alpha (1-z)^{n-1} \rho(z) dz,$$

or equivalently,

$$\int_{\text{core}(T_i)} (1 - \bar{t})^{n-1} d\mathbf{t} = \frac{\rho_i(1)}{\rho(1)} \int_0^\alpha (1-z)^{n-1} \rho(z) dz. \quad (*)$$

First of all, note that the left-hand-side of (*) could be rewritten as a double integration over $\text{core}_z(T_i) = \{\mathbf{t} \in \text{core}(T_i) : \bar{t} = z\}$ and then for z from 0 to α :

$$\int_{\text{core}(T_i)} (1 - \bar{t})^{n-1} d\mathbf{t} = \int_0^\alpha dz \int_L (1-z)^{n-1} d\text{core}_z(T_i) = \int_0^\alpha (1-z)^{n-1} dz \int_L d\text{core}_z(T_i),$$

where $\int_L dS$ is the Lebesgue integration over a set S . In particular, $\int_L d\text{core}_z(T_i)$ is the $(m-1)$ -dimensional volume of the set $\text{core}_z(T_i)$, denoted as $\rho_i(z)$.

Then consider the ratio between $\rho_i(z)$ and the volume of set $\text{core}_z(T)$, $\rho(z)$. Since both $\text{core}(T_i)$ and $\text{core}(T)$ are the intersections of the core and positive cones in \mathbb{R}^m , hence $\rho_i(z)$ and $\rho(z)$ must be proportional to z^{m-1} accordingly:

$$\rho_i(z) = z^{m-1} \rho_i(1), \quad \rho(z) = z^{m-1} \rho(1).$$

Finally, we conclude that

$$\int_L d\text{core}_z(T_i) = \rho_i(z) = \frac{\rho_i(1)}{\rho(1)} \cdot \rho(z),$$

which then directly implies (*). □

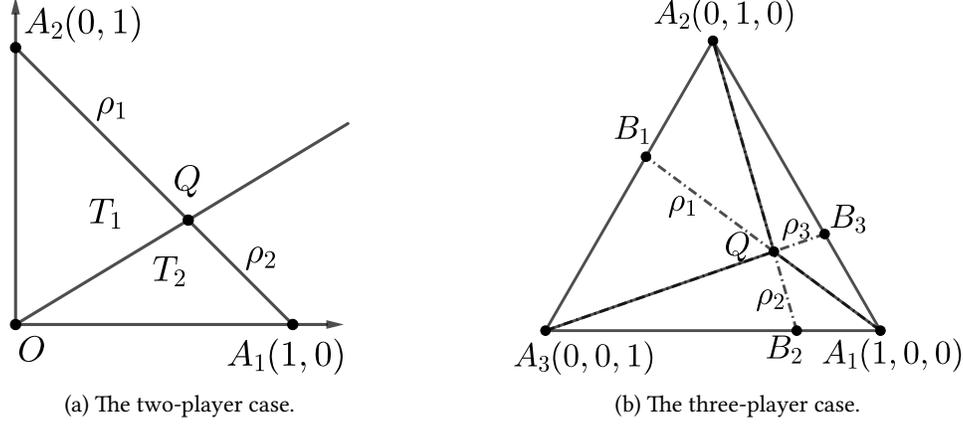

Figure 2: Simplexes for two-player and three-player cases.

Proof idea of Lemma 13 To smoothly proceed the analysis, we will start with the cases of $m = 2$ and $m = 3$.

For the two-player case (see Figure 2a), by definition,

$$T_1 = \{t \in [0, 1]^2 : t_1/x_1 \leq t_2/x_2\},$$

$$T_2 = \{t \in [0, 1]^2 : t_2/x_2 \leq t_1/x_1\}.$$

Therefore, the formula of the hyperplane (in fact a line in the 2-dimensional case) separating T_1 and T_2 is $t_1/x_1 = t_2/x_2$ and Q is the intersection of this line and the simplex A_1A_2 . In particular, the 1-dimensional volume of the set $\{t \in T_1 : \bar{t} = 1\}$ is exactly the length of the line segment QA_2 , which equals to $\rho_1(1) = \sqrt{2}x_1/(x_1 + x_2)$. Similarly, we get $\rho_2(1) = \sqrt{2}x_2/(x_1 + x_2)$.

For the three-player case (see Figure 2b), by definition,

$$T_1 = \{t \in [0, 1]^3 : t_1/x_1 \leq t_2/x_2, t_1/x_1 \leq t_3/x_3\},$$

$$T_2 = \{t \in [0, 1]^3 : t_2/x_2 \leq t_1/x_1, t_2/x_2 \leq t_3/x_3\},$$

$$T_3 = \{t \in [0, 1]^3 : t_3/x_3 \leq t_1/x_1, t_3/x_3 \leq t_2/x_2\}.$$

In this case, there are three hyperplanes separating T_1 , T_2 , and T_3 : $t_1/x_1 = t_2/x_2$, $t_2/x_2 = t_3/x_3$, and $t_3/x_3 = t_1/x_1$. Note that the intersection of the three hyperplanes is a line, $t_1/x_1 = t_2/x_2 = t_3/x_3$, which then intersects with the simplex $A_1A_2A_3 = \{t : t_1 + t_2 + t_3 = 1\}$ at a point Q .

Therefore, the 2-dimensional volumes (or areas) $\rho_1(1)$, $\rho_2(1)$, and $\rho_3(1)$ are exactly the areas of triangles $\triangle QA_2A_3$, $\triangle A_1QA_3$, and $\triangle A_1A_2Q$, respectively. Note that $A_1A_2A_3$ is a regular 2-simplex, hence $A_2A_3 = A_3A_1 = A_1A_2$. Thus the ratios between the areas of the triangles equal to the ratios between the heights of the triangles, because their bases (A_2A_3 , A_3A_1 , A_1A_2) are of the same length.

We conclude that

$$\frac{\rho_1(1)}{\rho_2(1)} = \frac{d(Q, A_2A_3)}{d(Q, A_3A_1)}, \quad \frac{\rho_1(1)}{\rho_3(1)} = \frac{d(Q, A_2A_3)}{d(Q, A_1A_2)},$$

where d denotes the distance between a point and a line.

In the meanwhile, recall that the coordinate of point Q is:

$$\left(\frac{x_1}{x_1 + x_2 + x_3}, \frac{x_2}{x_1 + x_2 + x_3}, \frac{x_3}{x_1 + x_2 + x_3} \right),$$

and with some primary calculation, we know that

$$\frac{d(Q, A_2A_3)}{d(Q, A_3A_1)} = \frac{x_1}{x_2} \quad \text{and} \quad \frac{d(Q, A_2A_3)}{d(Q, A_1A_2)} = \frac{x_1}{x_3}.$$

In other words, $\rho_i(1)/\rho(1) = x_i/(x_1 + x_2 + x_3)$.

Finally, we generalize the observations above to get the proof.

Proof of Lemma 13. By the definition, T_1, \dots, T_m are separated by $\binom{m}{2}$ hyperplanes:

$$\forall i \neq j, t_i/x_i = t_j/x_j.$$

In particular, the intersection of them is a line and the line intersects the $(m-1)$ -simplex $A_1 \cdots A_m$ at a unique point Q , whose coordinate is:

$$Q : \left(\frac{x_1}{x_1 + \cdots + x_m}, \dots, \frac{x_m}{x_1 + \cdots + x_m} \right).$$

In the meanwhile, note that for each $i \in [m]$, point $A_j \in T_i$ for all $j \neq i$. Therefore, the set $\{t \in T_i : \bar{t} = 1\}$ is a $(m-1)$ -simplex, $A_1 \cdots A_{i-1} Q A_{i+1} \cdots A_m$ and its volume is proportional to the $(m-2)$ -dimensional volume of its base $A_1 \cdots A_{i-1} A_{i+1} \cdots A_m$ times its height (the distance between point Q and the base).

Because $A_1 \cdots A_m$ is a regular $(m-1)$ -simplex, the volumes of the bases for each i are the same. Therefore, $\rho_i(1)/\rho_j(1)$ equals to the ratios between the distances from Q to the corresponding bases. Based on the coordinate of Q , we conclude that the ratio equals to x_i/x_j . In other words,

$$\frac{\rho_i(1)}{\rho(1)} = \frac{\rho_i(1)}{\rho_1(1) + \cdots + \rho_m(1)} = \frac{x_i}{x_1 + \cdots + x_m}.$$

□

6 Missing Proofs

The following technical lemma is repeatedly used in the proofs.

Lemma 16. For all $x \in \mathbb{R}$, $e^x \geq 1 + x$.

Proof of Lemma 14. For the core part, because $\bar{t} < \alpha < n^{-2/3}$,

$$\begin{aligned} \prod_{i=1}^m (1 - t_i) &= 1 - \sum_i t_i + \sum_{i \neq j} t_i t_j + \cdots = 1 - \bar{t} + O(\bar{t}^2), \\ \prod_{i=1}^m (1 - t_i)^{n-1} &= (1 - \bar{t})^{n-1} \left(1 + \frac{O(\bar{t}^2)}{1 - \bar{t}} \right)^{n-1}. \end{aligned}$$

Since $n\bar{t}^2 \leq n\alpha^2 < n^{-1/3}$, then by Lemma 16 and Taylor's expansion of e^x at 0,

$$\prod_{i=1}^m (1 - t_i)^{n-1} \leq (1 - \bar{t})^{n-1} e^{\frac{O(\bar{t}^2)}{1 - \bar{t}} \cdot (n-1)} = (1 - \bar{t})^{n-1} \cdot \left(1 + \frac{O(\bar{t}^2)(n-1)}{1 - \bar{t}} + O(n^2 \bar{t}^4) \right) = (1 - \bar{t})^{n-1} + O(n\bar{t}^2).$$

Thus

$$\int_{\text{core}(T_i)} f(t) dt \leq \int_{\text{core}(T_i)} n^m ((1 - \bar{t})^{n-1} + O(n\bar{t}^2)) dt,$$

where

$$\int_{\text{core}(T_i)} n^m \cdot O(n\bar{t}^2) dt \leq n^{m+1} \int_{\text{core}} O(\bar{t}^2) dt.$$

Consider rewrite the right-hand-side as a double integration over $\text{core}_z = \{t \in \text{core} : \bar{t} = z\}$ and then for z from 0 to α :

$$\int_{\text{core}} O(\bar{t}^2) dt = \int_0^\alpha O(z^2) dz \int_L d\text{core}_z$$

Note that $\int_L d\text{core}_z$ is the Lebesgue integration over the set core_z and hence equals to its $(m - 1)$ -dimensional volume, which is $\rho(z) = \frac{\sqrt{m}}{(m-1)!} \cdot z^{m-1}$ [Stein, 1966]. Therefore,

$$\int_{\text{core}} O(\bar{t}^2) dt = \int_0^\alpha O(z^2) \cdot z^{m-1} dz = O(\alpha^{m+2}).$$

That is

$$\int_{\text{core}(T_i)} n^m \cdot O(n\bar{t}^2) dt \leq O(n^{m+1} \alpha^{m+2}).$$

In summary,

$$\int_{\text{core}(T_i)} f(\mathbf{t}) dt = \int_{\text{core}(T_i)} g(\mathbf{t}) dt + O(n^{m+1} \alpha^{m+2}).$$

□

Proof of Lemma 15. For the tail part, according to the inequality of arithmetic and geometric means,

$$\prod_{i=1}^m (1 - t_i) \leq (1 - \bar{t}/m)^m,$$

then by Lemma 16 and $\bar{t} \geq \alpha$,

$$\prod_{i=1}^m (1 - t_i)^{n-1} \leq (1 - \bar{t}/m)^{m(n-1)} \leq e^{-\bar{t}(n-1)} \leq e^{-\alpha(n-1)}.$$

Therefore, $f(\mathbf{t}) \leq n^m e^{-\alpha(n-1)} = e^{-\alpha(n-1) + m \ln n}$. Also note that $\int_{\text{tail}} d\mathbf{t}$ is the volume of tail, which is less than 1, hence

$$\int_{\text{tail}(T_i)} f(\mathbf{t}) dt \leq e^{-\alpha(n-1) + m \ln n} \int_{\text{tail}} d\mathbf{t} \leq e^{-\alpha(n-1) + m \ln n}.$$
